	86	Objective: Phaeochromocytomas (PCC) and paragangliomas (PPGL) are rare, but strongly
	87	heritable tumours. Variants in succinate dehydrogenase (SDH) subunits are identified in
	88	approximately 25% of cases. However, clinical and genetic information of patients with SDHC
	89	variants are under-reported.
39 40	90	Design: This retrospective case series collated data from 18 UK Genetics and Endocrinology
41 42 43	91	departments.
44 45	92	Patients: Both asymptomatic and disease-affected patients with confirmed SDHC germline
46 47	93	variants are included.
48 49	94	Measurements: Clinical data including tumour type and location, surveillance outcomes and
50 51 52	95	interventions, SDHC genetic variant assessment, interpretation, and tumour risk calculation.
53 54	96	Results: We report 91 SDHC cases, 46 probands, and 45 non-probands. Fifty-one cases were
55 56	97	disease-affected. Median age at genetic diagnosis was 43 years (range:11-79). Twenty-four
57 58	98	SDHC germline variants were identified including six novel variants. Head and neck

paraganglioma (HNPGL, n=30, 65.2%), extra-adrenal paraganglioma (EAPGL, n=13, 28.2%)) and PCC (n=3, 6.5%) were present. One case had multiple PPGLs. Malignant disease was ٦ reported in 19.6% (9/46). Eight cases had non-PPGL SDHC-associated tumours, six gastrointestinal stromal tumours (GIST) and two renal cell cancers (RCC). Cumulative tumour risk (95% CI) at age 60 years was 0.94 (CI:0.79-0.99) in probands, and 0.16 (CI:0-0.31) in nonprobands respectively. Conclusions: This study describes the largest cohort of 91 SDHC patients worldwide. We confirm disease-affected SDHC variant cases develop isolated HNPGL disease in nearly 2/3 of patients, EAPGL and PCC in 1/3, with an increased risk of GIST and RCC. 1/5 developed malignant disease, requiring comprehensive lifelong tumour screening and surveillance. SDHC phaeochromocytoma and paraganglioma: a UK-wide case series

Introduction

Phaeochromocytoma and paragangliomas (PPGL) are rare, but strongly heritable neuroendocrine tumours that are associated with a number of hereditary syndromes. European studies suggest the incidence is approximately 0.6 cases per 100,000 person years.¹ The WHO guidelines use anatomical location to classify PPGL tumours into adrenal-gland phaeochromocytoma (PCC), accounting for 80% of PPGL disease and extra-adrenal paraganglioma (EAPGL) accounting for 20%.^{2,3} EAPGL are subdivided into sympathetic paraganglioma (PGL), associated with catecholamine secretion, and parasympathetic derived head and neck PGL (HNPGL) that rarely exhibit catecholamine secretion.

Over 40% of PPGL patients who undergo genetic testing are found to have a germline heterozygous pathogenic variant in a PPGL susceptibility gene.⁴ Germline loss-of-function variants affecting genes encoding subunits of succinate dehydrogenase (SDH), which also functions as Complex II in the electron transport chain, are identified in 25% of PPGL cases, resulting in different autosomal dominant syndromes.⁵ Loss of SDHB expression is detectable when any component of the SDH complex is inactivated, but no specific, validated SDHC-specific immunohistochemistry (IHC) exists.⁶

In the UK, patients with PPGLs are recommended to be referred for genetic counselling. Genomic testing is available if they fulfil National Genomic Test Directory criteria.^{7,8} Eligible patients are currently offered an 11 PPGL panel genomic test (SDHA, SDHB, SDHC, SDHD, SDHAF2, FH, MAX, MEN1, RET, TMEM127 and VHL). Variants of unknown significance (VUS) are reported in approximately 10% of PPGL diagnostic tests. If a pathogenic variant is

identified, familial cascade genetic screening testing can be offered. Surveillance of asymptomatic relatives includes Magnetic Resonance Imaging (MRI) and biochemical testing for catecholamine secretion, to aid early detection of tumours.⁷ The optimal surveillance programme is debated and numerous protocols exist.^{9,10}

SDHx-associated disease characteristics vary according to the pathogenic SDH-subunit. SDHB variants are most prevalent, accounting for 10% of PPGL cases, SDHD variants 5%-9%, SDHC 1-2% and SDHA <1%.9 SDHB variants are most common in patients with PCC or EAPGL. while SDHD variants frequently present with multifocal HNPGL.¹¹ The risk of aggressive, malignant disease is highest in patients SDHB pathogenic variants.¹² SDHC PPGL-associated pathogenic variants are less frequent than SDHD or SDHB, predominantly presenting with HNPGL disease at a younger age.^{11,13,14} Less is known about SDHC-associated disease, with respect to clinical behaviour, disease penetrance, non-PGL associated pathology and optimal surveillance.

There are three objectives of this nationwide series: First to describe the demographic, clinical and treatment data for both proband and non-proband individuals. Secondly to report genetic variants implicated in SDHC-associated PPGL disease and use structural analyses to evaluate pathogenicity in novel variants. Thirdly, to evaluate current surveillance practice and make recommendations for future care, based on the data presented.

Materials and methods

This retrospective study presents genetic and clinical information of germline SDHC variants (OMIM 602413, reference sequence NM 003001.3), diagnosed before March 2020, from 18 UK centres. An invitation to participate was sent to 23 UK centres in April 2019 (see

Appendix). Follow-up ended March 31st 2020, or if lost to follow up, date of last hospital
contact, or on death. The survey was registered as a service evaluation project 9649 at Guy's
and St Thomas' NHS Trust, London. A subgroup from 43 cases with *SDHC* intragenic variants
had been published previously.¹¹

179 Clinical Surveillance

Participating centres reported clinical information: age and date of diagnosis, and if affected, 180 PPGL characteristics including size, anatomical location, malignancy (defined as the presence 181 182 of disease in a lymph node or more distant site where chromaffin cells are not present, i.e. metastatic disease), required interventions and presence of other tumours. In the UK, prior to 183 March 2019, there was no consensus on the optimum surveillance programme for individuals 184 with SDHx germline variants, including SDHC for either affected individuals, or asymptomatic 185 carriers. Therefore, we asked centres to report on duration, interval between review and modes 186 of surveillance and screening outcomes. Standard biochemical tests differed by centre (24-hour 187 urine or plasma metadrenalines (MA), normetadrenaline (NMA) and/or 3-methoxytyramine 188 testing (3MT)). 189

0 190

60

191 Genetic Testing

Genetic variants were identified using standard molecular techniques (Sanger sequencing, multiplex ligase probe amplification or massively parallel sequencing via next generation sequencing or exome sequencing). Germline variants were reported according to American College of Medical Genetics and Genomics guidelines (ACMG).¹⁵ Centres reported germline variants, proband status, whether they were from a known *SDHC* kindred and additional PPGL variants, if found. Reported variants were compared against variants in NIHR ClinVar registries.¹⁶

40 41 42	215	Results
43 44	216	Demographic features
45 46	217	A total of 91 SDHC variant cases from 18 UK centres were included. See Table 1. There were
47 48 49	218	41 males (45%) and 50 females (55%), median age at genetic diagnosis 43 years (range: 11-
49 50 51	219	79). Forty-six (51%) cases were probands, 45 (49%) were relatives identified through cascade
52 53	220	testing from 22 kindreds. Fifty-one cases (56%) were disease-affected, 40 (44%) were
54 55 56	221	unaffected. The 51 disease-affected cases median age at diagnosis was 43 years (range: 12-79).
57 58 59 60	222	Unaffected cases (n=40) were younger with a median age at genetic diagnosis of 38 years

Clinical Endocrinology

(range: 11-79). Three non-probands had *SDHC*-associated disease (HNPGL (n=2) and PA
(n=1)) diagnosed prior to predictive testing.

226 Clinical features

There were 46 PPGL tumours diagnosed in 45 SDHC variant cases (Table 1), 65.2% were HNPGL, 6.5% thoracic PGL, 21.7% abdominal PGL and 6.5% PCC. HNPGLs were most frequent (n=30), located as follows: six carotid body (CBT), nine jugular, six vagal, one nasopharyngeal and eight HNPGL (site unspecified). Eleven cases (21.6%) developed SDHC-associated tumours: GIST (n=6, all female), Pituitary Adenoma (PA, n=3) and RCC (n=2). Of these, five cases presented with associated tumours, but no PPGL (GIST n=3, RCC n=1, PA n=1). Three GIST tumours showed SDHB immunonegativity and another was confirmed as wild-type. Eleven patients had multiple tumours: HNPGL and PA (n=2), HNPGL and thoracic PGL, thoracic PGL and adrenal adenoma, multiple RCCs, and GIST with either EAPGL (n=3), pulmonary chondroma (n=2) or oesophageal leiomyoma. Additional tumours include meningioma and bilateral breast cancer (see Supplementary Table 1 and Supplementary Table 2).

Malignant disease was identified in 19.6% (9/46) PPGL cases (Table 1). Where tumour sizes were recorded, all malignant HNPGL were >50mm, including two vagal tumours. Two cases had malignant EAPGLs, the youngest with a 45mm tumour aged 12, another aged 30 with a 78mm tumour, who died from metastatic disease aged 36. There were eight malignant *SDHC*related tumours (six GISTs, two RCCs).

In the disease-affected group, fifty interventions were recorded from 1977 to 2019 across 37
cases (Table 1). Main treatment modalities included surgical resection (n=33), radiotherapy

intervention (n=8) and active surveillance (n=13). Radiotherapy interventions included external beam radiotherapy, stereotactic radiotherapy and gamma knife radiosurgery. Nine HNPGL (30% of HNPGLs), two thoracic PGL, and two GIST cases remain on active surveillance.

Tumour incidence

Tumour incidence for probands with PPGL or GIST (n=37) and non-proband SDHC pathogenic variant cases (n=45) is shown in Figure 1. SDHC tumour incidence at age 40 and 60 years was 40.5% and 94.6% in probands, and 4.4% and 6.7% in non-probands respectively. Cumulative risk (95% CI) at age 20, 40 and 60 years was 0.05 (CI:0-0.12), 0.4 (CI:0.22-0.54) and 0.94 (CI:0.79-0.99) in probands, and 0, 0.08 (CI:0-0.18) and 0.16 (CI:0-0.31) in non-probands respectively (see Supplementary Figure 2). Age of diagnosis comparison between probands and non-probands (unpaired Student's t-test with two-tailed p value) p value = 0.178. 95% C.I. = 0 to 27.01. Difference between means (non-probands - probands) \pm SEM = 10.91 21.C \pm 7.957.

Surveillance

Screening information dates from 2006, with centres reporting imaging and biochemistry according to local protocols, (biochemical monitoring and imaging every 12-36 months). See Table 2. Imaging modalities included whole body (WB-)MRI from skull base-pelvis, abdominal Ultrasound scan. Information regarding Computed Tomography and sequence/nature of imaging protocols was not gathered. Biochemical modalities included either 24-hour urine or plasma metanephrines measurement. Chromogranin A data was not collected unless additionally reported by the centre.

Page 13 of 35

Clinical Endocrinology

Across the whole cohort, 68 (75%) had at least two rounds of surveillance screening using cross-sectional imaging, predominantly WB-MRI. Forty-two (46%) individuals had at least two rounds of biochemical testing. Seven of 51 disease-affected cases (13.7%, two HNPGL, five EAPGL) had raised biochemistry at diagnosis (elevated MA, or NMA or 3-MT). The overall median length of surveillance was 42 months (3.5 years, range: 4-107 months).

Surveillance data for 40 out of 45 non-proband asymptomatic individuals was available for a median period of 45.5 months (3.8 years). Five individuals were awaiting screening. Two individuals had tumours detected at baseline screen (5%), whereas 38 individuals had no tumours identified (95%). Twenty individuals had at least two rounds of cross-sectional imaging, 23 had at least two rounds of biochemical testing, without additional tumours identified (Table 2).

The eldest non-proband, diagnosed aged 79, had raised NMA and an EAPGL and GIST identified on MRI. After EAPGL surgery, the individual had annual MRI surveillance, with the GIST remaining stable. Another non-proband aged 60 had a CBT and thoracic PGL diagnosed on MRI and fully characterised by ¹⁸FDG-PET scan. The CBT was excised and the thoracic PGL has been monitored by MRI. Their PGLs showed no malignant features, with sizes smaller than average in this cohort: thoracic PGL 21mm; EAPGL 38mm (EAPGL and PCC tumour size average 45.5 + 25.1mm); HNPGL 22mm (HNPGL tumour size average 32.9 + 16.9mm) (Supplementary Table 1 and Supplementary Table 2).

Surveillance data for 46 proband individuals (following diagnostic investigations) was
available for a median period of 26 months (2.17 years, range: 4-107 months). Thirty-five
probands had at least one subsequent surveillance screen: 34 individuals had at least one screen

with cross-sectional imaging, 34 individuals had at least one screen including biochemical
testing. Twenty-four individuals underwent at least two rounds of cross-sectional imaging. No
new PPGLs were identified.

302 Genetic Variants

Twenty-four genetic *SDHC* variants were identified, including four single exon deletions, 19 intragenic variants and one intronic variant distributed along the entire coding sequence of the gene (see Table 3 and Figure 2). Eighteen *SDHC* variants have previously been described. Six *SDHC* variants are novel: three exon deletions (exon 4 deletion, c.371_372del. p.(Leu124fs), and exon 5 deletion), two missense variants (*SDHC*:c.200T>A, p.(Met67Lys) and *SDHC*:c.257G>A, p.(Gly86Asp)), and an intronic variant *SDHC*:c.(241+9)-(241+10)del.

The 5'-UTR variant *SDHC*:c.-38G>A initially reported as a VUS, was reclassified as benign (Table 3). Three cases had additional *SDHx* variants, none classified as pathogenic. One individual with PCC aged 39 had two pathogenic variants, *SDHC*:c.148C>T, p.(Arg50Cys) and *RET*:c.2410G>A, p.(Val804Met). They underwent adrenalectomy and thyroidectomy, where no C-cell hyperplasia or medullary thyroid cancer was found. PCC occurs rarely in RET V804M cases.²⁴ LOH analysis of PCC tumour showed normal *SDHC* results, indicating RET V804M may have driven PCC development.

All 11 missense coding variants were assessed according to ACMG guidelines, five (45.4%) met criteria for likely pathogenic variants, whilst five (45.4%) are VUSs and one is considered likely benign (Table 4). Overall, 16 out of 24 *SDHC* variants identified are considered pathogenic or likely pathogenic, six are VUSs and two are benign. Genotype-phenotype correlations are included in the appendix.

323	
324	Structure-phenotype correlation
325	All missense variants are predicted to have a destabilising effect on SDHC complex formation
326	(Table 4). The two novel variants SDHC:c.200T>A, p.(Met67Lys) and SDHC:c.257G>A,
327	p.(Gly86Asp) are predicted to destabilise protein structure and SDH complex formation. Both
328	variants are predicted to be 'damaging' and 'pathogenic' by PolyPhen2 and SIFT scores.
329	HNPGL tissue from c.257G>A, p.(Gly86Asp) showed SDHB immunonegativity. The
330	missense mutation most disruptive to complex formation (c.148C>T, p.(Arg50Cys)) disrupts
331	the N-terminus flexible loop, which is critical for the for both the assembly and stability of
332	Complex II. ²³ The most destabilising missense mutation (c.377A>G, p.(Tyr126Cys)) results in
333	a switch of bulky, hydrophobic tyrosine for a polar cysteine and interrupts strong stacking
334	interactions within a hydrophobic pocket, which are important for the stability of the helical
335	membrane anchor. ²³ The two missense mutations predicted to not affect protein structure
336	stability (c.214C>T, p.(Arg72Cys) and c.380A>G, p.(His127Arg)) both correspond to heme
337	complex binding residues, with the latter being directly coordinated to the iron centre. The fact
338	that the variant residues retain a degree of polarity, and that other coordinating residues remain
339	intact, may explain the relative redundancy in protein stability in these variants. One variant
340	SDHC:c.490A>T, p.(Met164Leu) was predicted to have a stabilising effect on protein
341	structure, predicted to be 'tolerated'/'benign' by structural analysis and classified as 'likely
342	benign' by ACMG guidelines. In this case, the PCC tumour showed SDHB immunopositivity.
343	

344 Discussion

This multi-centre, nationwide UK case-series describes the largest *SDHC* cohort to date. The median age of genetic diagnosis for disease-affected cases was 43 years (range: 12-79), similar to that reported by Schiavi *et al.* (median 46 years, range: 13-73), younger than cases with
sporadic HNPGL (median 53 years, range: 15-83).¹³

> As reported previously, we recorded a wide spectrum of tumours in SDHC-associated disease.¹¹ We confirm the majority of SDHC cases develop isolated HNPGL (65.2%), with EAPGL in 28.2%, and PCC in 6.5%. HNPGL are more common in SDHD (85%) than SDHC but less common in SDHB (35%). ⁹ Previous studies reported 36% SDHC cases had multiple PPGLs, however only one UK SDHC case had multiple PPGLs.⁹ While SDHC cases have been described as developing benign HNPGLs, six cases developed malignant HNPGLs (20%), >50mm at diagnosis.^{13,25} Two metastatic EAPGL cases presented young (12 and 30 years), with tumours >45mm. These features are all predictors of aggressive disease. In a recent meta-analysis, patients with SDHC tumours were reported to have a metastatic risk of 23% (CI: 0.10-0.45) over an averaged follow-up period of 4.8 years.²⁶ Our marginally lower overall metastatic PPGL rate of 19.6%, may reflect our slightly shorter follow-up period, averaged at 3.1 years. The risk of malignant disease at 19.6% remains lower than the pooled risk in SDHB (31%), but higher than in SDHD (8%).²⁶

) 363

Our case series identified rarer tumours associated with *SDHC*: GIST, PA and RCC in 21.5% of cases.²⁷ GIST was the second most common tumour after PPGL. Interestingly, five of the six cases with GIST had related tumours, e.g. EAPGL (confirming Carney-Stratakis syndrome), or pulmonary chondroma and oesophageal leiomyoma, evidence of incomplete Carney's Triad. Unfortunately, there was no *SDHB* IHC testing in RCC or PA cases, so SDHdeficiency remains unconfirmed. Whilst PA have been reported in *SDHC* cases, they occur commonly in the general population at a frequency of 1 in 1,064 cases.²⁸ The association of

pituitary tumours as a feature of SDHC-related disease may therefore represent an incidental finding. We describe six novel germline SDHC variants: Three pathogenic exon deletions, two missense VUS and one intronic variant. In silico structural analyses of all missense variants correlated with pathogenicity classification for previously identified variants and demonstrated disruption of key structural and functional elements of the SDH complex. Structural analyses predict novel variants SDHC:c.200T>A, p.(Met67Lys) and SDHC:c.257G>A, p.(Gly86Asp) to be pathogenic, correlating with SDHB immunonegativity in the *SDHC*:c.257G>A, p.(Gly86Asp) case.

Reclassification of variants is a dynamic process and can have important implications for clinical practice. One patient with an EAPGL has the non-coding variant SDHC:c.-38>A, designated a VUS in 2008, but reclassified as a benign variant in 2018. SDHC:c.148C>T, p.(Arg50Cys), and c.377A>G, p.(Tyr126Cys) were initially reported as VUSs, but recently reclassified (in 2018 and 2021) as 'likely pathogenic', affecting nine probands. Reclassification events are increasing, with one commercial laboratory reporting 7.7% of unique VUS being reclassified over 10 years.²⁹ Upgrades from a VUS to a pathogenic variant will have clinical consequences. Downgrades may be helpful in releasing patients from unnecessary surveillance. Overall, 16 out of 24 SDHC variants identified are currently considered pathogenic or likely pathogenic, with six remaining as VUSs and two now considered benign.

393 Screening outcomes were reported for all *SDHC* variant cases. Relatively few cases with 394 disease had a positive biochemical result (13.7%). This is unsurprising, reflecting the 395 propensity for *SDHC* patients to develop HNPGL, which are often non-secretory, underlining the importance of imaging in PPGL detection. During follow-up, no metachronous tumours
were identified in probands, but tumour growth and progression of metastatic disease was
observed.

All tumours found in asymptomatic non-proband cases were identified at initial work-up: three PGLs and a GIST in two cases, detected by MRI. Reassuringly their PGL tumour sizes were smaller than the averages across the cohort, indicating surveillance had detected disease earlier, with possible beneficial outcomes. However, with only one GIST case in non-probands, the penetrance of this tumour remains unclear. The range of treatments employed reflects the changing practice for treating HNPGL disease. HNPGLs are slow-growing tumours with a doubling time of 5.8 years.³⁰ Many patients with HNPGLs are now being considered for nonsurgical therapy instead of operative intervention, which risks increased morbidity to achieve surgical cure.³¹ The broadened range of radiation techniques available and their success, for example ablative stereo-tactic radiosurgery, has led to increased use of these interventions. Discussion via a National MDT for managing HNPGLs in SDHC, in view of the 20% HNPGL malignancy risk, could provide a mechanism to enhance practice and outcomes.

This study reports SDHC tumour incidence at age 40 and 60 years was 40.5% and 94.6% in probands, and 4.4% and 6.7% in non-probands respectively. This is in keeping with the published findings of Benn et al., who report predicted lifetime penetrance of 8.3% (95% CI 3.5% to 18.5%), among patients selected for known SDHC pathogenic or likely pathogenic variants.³² This study highlights low cumulative tumour risk in non-probands, 16% (95% CI:0-0.31) at 60 years compared to a previous estimate of 25% (95% CI 0-0.57).¹¹ This may reflect the younger average age of non-probands at 38 years, compared to the average age of affected cases at 43, with tumours yet to develop in non-probands. Certainly, for proband cases, tumours

Clinical Endocrinology

presented throughout life and metastatic disease was seen at all ages, emphasizing lifelongtumour susceptibility.

The aim of any surveillance programme in *SDHC* patients at risk of PPGL, GIST and RCC is to detect early disease and reduce the chance of metastatic spread.¹¹ However, with low tumour incidence in non-probands and lower metachronous tumour risk in probands than previously documented, surveillance frequency might safely be lengthened from recommended biennial cross-sectional imaging, thus reducing costs and the burden to patients of frequent scans.⁷ Recent screening studies also confirm low tumour rates in asymptomatic SDHC carriers with 4% (1/28) having PPGL diagnosed at baseline,³³ matching our experience of 5% (2/40) cases identified.

In 2016, the European Society for Endocrinology published a clinical practice guideline for patients operated on for PPGL tumours, including any genetic variants. It recommended assaving plasma or urinary MN and 3MT every year, and performing imaging tests every 1-2 years in patients with biochemically inactive PPGL, to screen for local or metastatic recurrence or new tumours.³⁴ While this has been broadly adopted for patients with other *SDHx* variants (i.e. *SDHB*)⁹, evidence from our surveillance data suggests this was not routinely achieved for SDHC cases across the UK prior to 2020. Following the results of this study, we recommend: 1. Lifelong tumour specific follow-up (to monitor recurrent or metastatic disease, as determined by specialist multidisciplinary teams) for affected patients. 2. For metachronous PPGL and RCC detection, annual clinical review with plasma metanephrines, and WB-MRI (skull base, neck, thorax, abdomen and pelvis) 3-5 yearly.

444 To identify GISTs, gastric symptoms should be enquired of at clinical review and a full 445 blood count (FBC) measurement taken to assess for anaemia. For patients with **Clinical Endocrinology**

1 2		
2 3 4	446	suggestive symptoms or anaemia, Oesophageal-Gastro-Duodenoscopy (OGD) should
5 6	447	be considered.
7 8 9 10 11 12 13 14 15 16 17 18	448	3. Non-probands commence annual clinical review with biochemistry and FBC from 10
	449	years, and WB-MRI, as above, from 15 years.
	450	4. Patients with a SDHC VUS and PPGL continue tumour specific follow-up. For their
	451	potential metachronous tumour risk, annual clinical review with biochemistry and FBC
	452	for 10 years, and WB-MRI, as above. Assessment of SDHC VUS status to determine if
19 20	453	lifelong WB-MRI surveillance is indicated after 10 years (provided there are no high-
21 22	454	risk features, e.g. multiple PPGLs or familial disease).
23 24 25 26 27 28 29 30 31 32	455	5. SDHB immunohistochemistry, molecular analysis (LOH studies or somatic testing),
	456	histopathological review and consideration of tumour methylome and metabolomics
	457	profiling in PPGL and additional tumours, to aid variant classification and determine
	458	whether tumours are truly <i>SDHC</i> -related. ²⁷
33 34	459	
34 35 36 37 38	460	Despite this study being the largest SDHC patient cohort reported, we recognise its limitations,
	461	including retrospective data collection, incomplete clinical information and the challenge of
40 41	462	case ascertainment. Our short follow-up period may not have captured all tumour occurrences
42 43	463	or metastatic disease and the small numbers in the cohort may have insufficient power for some
44 45	464	differences to be realised. At present, there is no UK register for patients with SDHx disease,
46 47 48	465	their surveillance outcomes or impact of surveillance on morbidity and mortality. Such a
49 50	466	register would also benefit from access to centralised genomics data and cancer registration,
51 52	467	which would provide a richer overview of SDHC-associated disease.
53 54 55	468	
56 57	469	In summary, this UK multi-centre study reports the largest dataset of 91 affected and unaffected
58 59	470	SDHC germline variant carriers to date, with six novel SDHC variants out of 24 identified. The

[4] Supplementary Figure 1: BLAST alignment of Human Succinate dehydrogenase
cytochrome b560 subunit, SDHC (Q99643) and Pig SDHC (D0VWV4).³⁵ Structural prediction
analyses were based on the high-resolution 1ZOY structure of succinate dehydrogenase from *Sus scrofa* (https://www.rcsb.org/structure/1zoy, PMID: 15989954).

[5] Supplementary Figure 2: Cumulative tumour risk and 95% CI for probands and nonprobands with pathogenic variants in *SDHC* with median ages for both groups highlighted. NB:
Due to limited number of older non-probands, the final value of the corresponding line is likely
to be over-inflated (95% CI: 0-89.6%).

677 Appendix

[1] Supplementary information regarding centres approached. An invite was initially sent to 23 genetics centres in the UK and these departments linked us to relevant endocrine services involved in the care of their SDHC families. Genetic centres in Aberdeen, Bristol, Dundee, Exeter, St George's Hospital (SW London) and University Hospital Southampton NHS Trust, Wessex did not have any known SDHC variant cases. The All Wales Genetic service was able to identify SDHC cases, but unable to provide any clinical information due to difficulties in locating information from patient records. There were 28 cases from London centres (Guy's and St Thomas' NHS Trust, King's College Hospital NHS Foundation Trust, Bart's Health NHS Foundation Trust, North West London Genetic Service, including Imperial College Healthcare Foundation NHS Trust and University College London Hospital NHS Foundation Trust). Outside of London, there were 63 cases in total from the following centres: Oxford University Hospital NHS Foundation Trust, Cambridge University Hospital Foundation NHS Trust, University Hospitals Birmingham NHS Trust, Nottingham University Hospitals NHS

Trust, Sheffield Teaching Hospitals NHS Foundation Trust, Leeds Teaching Hospitals NHS Trust, University Hospitals of Leicester, Manchester University NHS Trust, Newcastle Upon Tyne Hospitals NHS Foundation Trust, Edinburgh Royal Infirmary, Glasgow Royal Infirmary and Belfast City Hospital, Northern Ireland. The largest contributing centre in London was GSTT and outside of London was Newcastle.

[2] Supplementary information regarding genotype-phenotype evaluation. Bayley *et al.* reported that truncating SDHB and SDHD variants were significantly over-represented in affected cases, with SDHB/D truncations associated with higher risk of developing PPGLs, compared with missense variants.³⁶ In our SDHC cohort, truncating variants were not associated with PPGL over other disease sites (two-sided Fischer's exact test, p = 0.999, CI: 0.246-4.028), malignant disease (p=0.999, CI: 0.232-5.080), or development of non-PGL malignancy (GIST and RCC, p=0.683, CI: 0.069-3.637) (Supplementary Table 3). Given the small sample size per variant, it is not meaningful to associate predicted pathogenicity with tumour incidence in this cohort, although this has been demonstrated in SDHB and SDHD Y.C.M variants.11

Table 4: Variants reported from position chr 1.161328466.

^a The coexisting SDHD variant c.34G>A is registered on ClinVar as likely benign.

^b The coexisting SDHB variant c.8C>G is registered on ClinVar as a benign variant.

^c The coexisting SDHD variant c.319C>T is registered on ClinVar as a VUS.

g/ on 01/07/2021). ^d Allele frequencies are as reported in gnomAD v3.1.1 (accessed via https://gnomad.broadinstitute.org/ on 01/07/2021).
