14 **Key Words:** Coastal nitrogen; seabirds; penguins; temperate; sub-polar; NH₃
15 emissions; atmospheric dispersion; inverse modelling

16 Abstract

17 The chemical breakdown of marine derived reactive nitrogen transported to the land
18 as seabird guano represents a significant source of ammonia (NH₃) in areas far from
19 other NH₃ sources. Measurements made at tropical and temperate seabird colonies
20 indicate substantial NH₃ emissions, with emission rates larger than many
21 anthropogenic point sources. However, several studies indicate that thermodynamic
22 processes limit the amount of NH₃ emitted from guano, suggesting that the percentage
23 of guano volatilizing as NH₃ may be considerably lower in colder climates. This study
24 undertook high resolution temporal ammonia measurements in the field and coupled
25 results with modelling to estimate NH₃ emissions at a temperate puffin colony and
26 two sub-polar penguin colonies (Signy Island, South Orkney Islands and Bird Island,
27 South Georgia) during the breeding season. These emission rates are then compared
28 with NH₃ volatilization rates from other climates. Ammonia emissions were
29 calculated using a Lagrangian atmospheric dispersion model, resulting in mean
30 emissions of 5 µg m⁻² s⁻¹ at the Isle of May, 12 µg m⁻² s⁻¹ at Signy Island and 9 µg m⁻²
31 s⁻¹ at Bird Island. The estimated percentage of total guano nitrogen volatilized was
32 5% on the Isle of May, 3% on Signy and 2% on Bird Island. These values are much
33 smaller than the percentage of guano nitrogen volatilized in tropical contexts (31-
34 65%). The study confirmed temperature, wind speed and water availability have a
35 significant influence on the magnitude of NH₃ emissions, which has implications for
36 reactive nitrogen in both modern remote regions and pre-industrial atmospheric
37 composition and ecosystem interactions.

38 1. Introduction

39 Nitrogen is found in all living cells and is necessary for the growth and survival of all
40 living things. However, nitrogen in its most abundant form, diatomic nitrogen (N₂), is
41 a relatively un-reactive molecule and needs to be 'fixed' to become useable as
42 reactive nitrogen (N_r) compounds. N_r includes all N forms with the exception of N₂,
43 including ammonium and nitrate ions, gases such as nitrous oxide (N₂O), nitrogen
44 oxides (NO_x) and ammonia (NH₃) and organic nitrogen compounds. Human activities,

45 including the Haber-Bosch process, legume cultivation and fossil fuel combustion, are
46 estimated to create 210 Tg of plant-useable N_r annually (Fowler et al., 2013).
47 Reactive nitrogen added to the Earth's surface as fertilizer can wash off into the
48 hydrosphere, volatilize to the atmosphere as NH_3 or form organic nitrogen compounds
49 in soils. Further decomposition of oceanic, terrestrial, plant and animal N_r can
50 produce N_2 as well as NO_x and N_2O .

51 Studies suggest the emission of NH_3 gas is likely to negatively impact local
52 ecosystems causing acidification and eutrophication, which has been shown to alter
53 local interspecies competition and biodiversity (Cape et al., 2009; Sutton et al., 2011,
54 2012). Currently, the biogeochemical processes following the addition of seabird
55 derived N_r to the surface of land are not well understood. However studies have
56 reported NH_3 emission from poultry excreta which has similar properties to seabird
57 guano (Elliott and Collins, 1982; Harper et al., 2010) and a study of Adelie penguin
58 colony on the Antarctic continent suggests volatilized NH_3 creates a spatial impact
59 zone of up to 300 km² surrounding the colony where phosphomonoesterase activity is
60 increased in indigenous organisms (Crittenden et al., 2014). In order to be emitted as
61 NH_3 , excreted uric acid must first be hydrolysed under microbial decomposition to
62 produce ammonium and bicarbonate ions. Both the processes of uric acid hydrolysis
63 and NH_3 volatilization appear to be affected by environmental conditions, including
64 water availability and temperature (Nemitz et al., 2001; Sutton et al., 2013). Food
65 composition and pH may also play a significant role in NH_3 emission (Elliott and
66 Collins, 1982; Harper et al., 2010) where NH_3 emission depends on the ratio between
67 the nitrogen and energy content of the food (Wilson et al., 2004) and the pH affects
68 the rate at which uric acid is converted to ammonium (Elliott and Collins, 1982).

69 In a theoretical study on seabird N_r excretion by Riddick et al. (2012), the estimated
70 percentage of N_r that volatilizes (P_v) ranged from 9 % in colder temperatures (average
71 temperature during breeding season *c.* 5°C) to 100 % at colonies in higher
72 temperatures (> 19°C). Recent measurement-based estimates showed mean P_v values
73 of 31 to 65 % at two tropical seabird colonies estimated (Riddick et al., 2014).
74 Additionally, some variation in P_v is expected in relation to habitat, so that birds
75 nesting in vegetation and breeding in burrows (such as puffins), would show a lower
76 percentage emission as NH_3 as compared with birds nesting and breeding on bare
77 rock surfaces (Blackall et al., 2007; Riddick et al., 2012). Similarly, Zhu et al. (2011)
78 suggest temperature is an important driver in the production of NH_3 , however they
79 also suggest temperature may not be the sole climatic variable that affects NH_3
80 emission.

81 Seabird colonies are well suited for measuring NH_3 emissions because they are
82 generally remote from human activity, resulting in near-background NH_3
83 concentrations in the surrounding area. Biogeochemical processes are relatively
84 simple because the majority of seabirds nest on rocky surfaces where excreted guano
85 can: (1) build up on the surface; (2) decompose, converting uric acid to ammoniacal
86 forms which are liable to volatilization, or (3) be washed into the sea. As a model
87 system for studying the effect of climate/environment on NH_3 emissions, seabird
88 colonies also have the advantage that they are generally not influenced by human
89 management practices (other than those which may affect seabird numbers). In
90 addition to this, the penguin species' annual presence in the nitrogen poor regions of
91 the Southern Ocean supplies 858 Gg of N_r per year ($\sim 3 \text{ kg m}^{-2}$) in the form of guano
92 to the land (Riddick et al., 2012). In agriculture terms, the average penguin colony

93 receives 30,000 kg ha⁻¹ compared with 246 kg ha⁻¹ for fertilizer consumption on
94 arable land in the UK in 2015 (Worldbank, 2015).

95 As a result of these features, seabird colonies offer a system that is well fitted to
96 address the question of how NH₃ emission rates vary globally through different
97 climatic regimes as well as develop understanding of atmosphere-ecosystem
98 interaction in the natural world. The present study contributes to this question by
99 providing data on NH₃ emissions from seabird guano in temperate and sub-polar
100 conditions, for comparison with previous measurements in tropical conditions
101 (Riddick et al., 2014). By bringing these measurements together with other published
102 datasets, we are then able to investigate the global scale variation in NH₃ emission
103 rates.

104 **2. Methods and Materials**

105 **2.1 Ammonia measurements**

106 Two methods were applied in this study to make NH₃ concentration measurements:
107 (1) passive sampling and (2) an on-line active sampling NH₃ analysis instrument, as
108 summarized below.

109 The passive samplers used (ALPHA samplers, CEH Edinburgh) consist of a 23 mm
110 diameter sampler with a 6 mm diffusion path between a Teflon membrane and an
111 adsorbent sampling surface (filter-paper disc impregnated with citric acid). Further
112 details of ALPHA sampler and its system of pre- and post-sampling protective caps
113 are provided by Tang et al. (2001). In this study, triplicate samplers were used at each
114 sampling location and exposed for periods of 2 to 4 weeks. The samplers were
115 attached by Velcro to an upturned plant saucer (for protection) that was fastened to a
116 pole (The sampling heights above the ground for the different sites are described
117 below, with further details given in Supplementary Material 7). Aluminium strips
118 were mounted on top of each saucer to deter perching birds.

119 At all times, except during deployment, the ALPHA samplers were sealed in plastic
120 containers and refrigerated. In the laboratory, the NH₃ concentration of the air at the
121 seabird colony was determined using ammonium flow injection analysis, based on
122 selective diffusion of NH₃ across a Teflon membrane at high pH (FLORRIA,
123 Mechatronics, NL). Laboratory and field blanks were also analysed to ensure samples
124 were not contaminated. In the present study, the high sensitivity ALPHA samplers
125 were used with a Method Detection Limit (MDL) = 0.09 µg m⁻³ for two-weekly
126 exposure on Signy Island. A description of how the MDL was calculated is given in
127 Supplementary Material Section 1. ALPHA samplers were also deployed at Bird
128 Island and the Isle of May for comparison with the on-line measurements.

129 The on-line NH₃ concentration measurements were made with an AiRRmonia gas
130 analyser (Mechatronics, NL) on Bird Island and a Nitrolux 1000 gas analyser
131 (Pranalytica, USA) on the Isle of May. At each site air was drawn into the instrument
132 through 20 m PTFE tubing, to minimize NH₃ sticking the PTFE tubing was heated
133 and insulated a full description of the online active measurement set up is given in
134 Supplementary Material Section 3, with inlet flows of 8 l min⁻¹.

135 The AiRRmonia analyser (Norman et al., 2009) is based on a similar principle to the
136 FLORRIA. In this case, atmospheric air is passed over a first Teflon membrane with a
137 counterflow of dilute acid to allow gaseous NH₃ to transfer to aqueous ammonium in
138 solution. Sodium hydroxide is then added to liberate molecular NH₃, which then
139 diffuses across a second Teflon membrane into a counter flow of deionized water,

140 with reformed ammonium then detected by conductivity. The AiRRmonia has an
141 instrument delay time (the time taken between air sampling and instrument response)
142 of ~ 5 minutes with 15 min averages used to assure quantitative response, with a
143 Limit of Detection (LOD) of $\sim 0.1 \mu\text{g m}^{-3}$ and a MDL in this context of $0.07 \mu\text{g m}^{-3}$.
144 The AiRRmonia measurements were recorded every minute and then the data
145 averaged to 15 minute periods for application in the inverse dispersion model.
146 Calibration of the AiRRmonia was carried out every five days and agreed within 5%
147 over the periods of measurement.

148 The Nitrolux analyser is a photoacoustic instrument that uses absorption of NH_3
149 molecules from a line-tuneable CO_2 laser to measure concentration. The Nitrolux
150 1000, as used here, has a detection limit of $\sim 0.1 \mu\text{g m}^{-3}$, a MDL in this context of 0.1
151 $\mu\text{g m}^{-3}$, a range of $0.1 - 2000 \mu\text{g m}^{-3}$, and measures concentrations every 45 s. The
152 instrument delay time of the instrument is a function of temperature and relative
153 humidity (typically 4 (3-5) minutes), allowing the data to be averaged up to 15 minute
154 periods for application in the inverse dispersion model. The Nitrolux 1000 requires
155 six-monthly calibrations (Cowen et al., 2004).

156 **2.2 Field Methodology**

157 **Site 1: The Isle of May, Scotland**

158 The Isle of May (56.19°N , 2.56°W) is a nesting site for many seabird species,
159 including Common Guillemot (*Uria aalge*), Herring Gull (*Larus argentatus*), Arctic
160 Tern (*Sterna paradisaea*), Black-legged Kittiwake (*Rissa tridactyla*) and Atlantic
161 puffin (*Fratercula arctica*). The island is located at the entrance to the Firth of Forth
162 in eastern Scotland (Figure 1) and has a temperate climate (average temperature of
163 15°C , average humidity of 80% and average wind speed of 4 m s^{-1} during the
164 breeding season). Passive and active measurements of NH_3 concentrations and
165 meteorological parameters were made above Atlantic puffin burrows (Figure 1).
166 Atlantic puffins breed on vegetated slopes and amongst rocky outcrops, where they
167 dig and nest in 1-2 m long burrows. Atlantic puffins burrow in most parts of the Isle
168 of May with a colony total of 45,000 pairs during June and July 2009 (Harris et al.,
169 2009), with approximately 20,000 burrows in our study area, between the Low Light
170 and Kirk Haven (area shaded dark grey in Figure 1). Measurements were carried out
171 from 01/07/09 to the 06/09/09 during (July) and after (August and September) the
172 period of chick rearing, where large numbers of prospecting juvenile birds are present
173 in addition to breeding birds.

174 Active Sampling Campaign

175 The Nitrolux trace gas analyser measured NH_3 concentrations on-line over the
176 Atlantic puffin colony on the Isle of May from 30/06/09 to 23/07/09. The air inlet was
177 positioned 1.26 m above the ground at the measurement site (labelled in Figure 1).
178 Measurements during the Isle of May campaign were limited to daylight hours to
179 reduce disturbance to fledging puffins by the generator. Micrometeorological
180 parameters were measured using a Gill Windmaster Pro sonic anemometer on a mast
181 2.5 m above the ground. Meteorological data were collected by instruments on a mast
182 on the highest point of the island (Figure 1). Data collected included: air temperature,
183 relative humidity, solar radiation (all at 1 m above ground) and ground temperature
184 was using temperature sensors on the surface. The weather station was located away
185 from the colony to avoid interfering with birds' nesting behaviour.

186 <<INSERT FIGURE 1 HERE>>

187 Passive Sampling Campaign

188 Triplicate ALPHA samplers were used to measure NH₃ concentrations above the
189 Atlantic puffin colony (“Measurement Site”, as labelled in Figure 1), at a height of 1.5
190 m, for 4 periods of 15 days, as described in Supplementary Material Section 7A.
191 Meteorological data were collected by a weather station positioned at the highest
192 point of the island (Figure 1).

193 **Site 2: Bird Island, South Georgia**

194 Bird Island is part of South Georgia, 1000 km south-east of the Falkland Islands
195 (Figure 2). Ammonia concentrations were measured at the ‘Big Mac’ Macaroni
196 penguin (*Eudyptes chrysolophus*) colony at the western end of the island (54.0106 °S,
197 38.0753 °W), where 40,000 breeding pairs were present during the measurement
198 period from 07/11/10 and 26/12/10 (D. Briggs, British Antarctic Survey, pers.
199 comm.). Immediately to the east of the active measurement site, the ‘Little Mac’
200 colony is located (450 pairs of Macaroni penguin in a small satellite colony). The
201 average temperature was 3°C, average relative humidity 92 % and average wind
202 speed 5 m s⁻¹ during the measurement period.

203 Active Sampling Campaign

204 On-line NH₃ concentrations were measured at Fairy Point to the south of Big Mac
205 (Figure 2). The air inlet for the AiRRmonia analyzer was positioned at 2 m above the
206 ground. All the instruments were housed in a tent to provide protection from the
207 wind, precipitation, sea spray and sun. Micrometeorological parameters were
208 measured using a Gill Windmaster Pro sonic anemometer on a mast 2.5 m above the
209 ground. Meteorological data were collected by instruments on two masts on the
210 highest point at Fairy Point. Data collected included: air temperature, humidity and
211 solar radiation at 1 m above ground, and wind speed at three heights above ground
212 (0.5 m, 1 m, and 2 m). Ground temperature was measured using a Tiny Talk data
213 recorder placed on the ground (Supplementary Material Section 4).

214 <<INSERT FIGURE 2 HERE>>

215 Passive Sampling Campaign

216 Ammonia concentrations were recorded at nine locations on Bird Island using
217 ALPHA samplers mounted at 1 m above ground (Figure 2). These were exposed in
218 seven sampling periods of around 2 weeks from 07/11/2010 to 26/12/2010.

219 **Site 3: Signy Island, South Orkney Islands**

220 Signy Island is a small island in the South Orkney Islands in the Southern Ocean
221 (Figure 3). A relatively flat area on the Gourlay Peninsula was used for passive
222 sampling of NH₃ concentrations from 10/01/2009 to 21/02/2009 at a colony of 10,000
223 pairs of Adélie penguins (*Pygoscelis adeliae*) and 9,000 pairs of Chinstrap penguins
224 (*P. antarcticum*) (60.73° S, 45.59° W). Both species breed in snow free areas and
225 build rudimentary nests of small stones. The climate at this site represents sub-polar
226 conditions with average temperature of 2°C, average relative humidity of 84 % and
227 average wind speed of 5 m s⁻¹ during the breeding season.

228 ALPHA samplers were deployed at five locations (Mast 1 – 5, Figure 3) over three
229 separate sampling periods of 2 weeks each. Masts 1 and 2 had ALPHA samplers at 1
230 m and 1.5m from the ground. Mast 5 was located as far as possible from any birds to
231 sample background NH₃ concentrations, *en route* from the base at Borge Bay to

232 Gourlay (Supplementary Material 3). Representative meteorological data
233 (temperature, wind speed, relative humidity and precipitation) were obtained from the
234 nearest weather station, the Argentinean Orcadas Base on Laurie Island, South
235 Orkney Islands (US National Climatic Data Center (NCDC) Integrated Surface
236 Hourly (ISH) database; NCDC, 2011).

237 <<INSERT FIGURE 3 HERE>>

238 **2.3 Estimation of NH₃ Emissions**

239 Estimates of NH₃ emissions were calculated using an inverse application of the
240 WindTrax atmospheric dispersion model version 2.0 (Flesch et al., 1995). Given
241 potential temporal covariance between atmospheric NH₃ concentrations and
242 dispersion, such calculations should ideally be based on short-term measured
243 concentrations.

244 For input into WindTrax, both the on-line NH₃ concentrations and meteorological
245 data were averaged over 15 minutes to minimise any effects of turbulence while
246 preserving variation caused by environmental or atmospheric change (Laubach et al.
247 2008; Flesch et al. 2009). Fifteen minute averages of wind speed (u , m s⁻¹), wind
248 direction (WD , °), temperature (T , °C), NH₃ concentration at 2 m (X , µg m⁻³),
249 roughness height (z_0 , cm) and the Monin-Obukhov length (L , m) were used as input to
250 WindTrax.

251 For each on-line NH₃ concentration dataset, data were removed for calibration
252 periods, any periods when the instrument was not sampling the colony due to wind
253 direction and any periods of high atmospheric stability (wind speed, $u < 0.15$ ms⁻¹,
254 friction velocity, $u_* < 0.1$ ms⁻¹ and Monin-Obukhov Length $|L| < 2$). Each WindTrax
255 simulation used 50,000 particle projections to back-calculate the NH₃ emission.

256 While the first focus of the emission calculations was on applying the on-line NH₃
257 concentration measurements, it is also of interest to assess how the inverse model
258 performs when using time-integrated NH₃ concentrations, since it is not always
259 feasible to deploy on-line NH₃ instrumentation (e.g. as at Signy Island). For this
260 reason, we also applied the Windtrax model using two-weekly averaged NH₃
261 concentrations, coupled with the time-resolved estimates of atmospheric turbulence.
262 In principle, this relaxation is expected to contribute significant errors in the resulting
263 flux estimates. However, experience under other conditions indicates that these errors
264 may be small when compared with other sources of error or with the difference in
265 emission rates between sites (Riddick et al., 2014; Theobald et al., 2013). The
266 deployment of both passive and active sampling at the Isle of May and at Bird Island
267 allowed comparison these two approaches, providing a basis to assess confidence in
268 the passive measurements at Signy Island, where only the passive NH₃ concentration
269 data were available.

270 The comparison of estimated NH₃ emissions calculated using the passive and on-line
271 sampling methods can also be used to provide an indicative estimate of the respective
272 sources of error in each approach (Riddick et al., 2014). To do this, the concentrations
273 recorded by the on-line continuous NH₃ detector are first averaged for the same
274 periods as the passive ALPHA sampler data, and then used to estimate NH₃ fluxes
275 using the WindTrax system. The difference in mean flux between the approach using
276 15 minute NH₃ concentrations and the 2-weekly averaged data from the on-line
277 system gives an estimate of the micrometeorological error associated with low-time
278 resolution NH₃ concentration data. By comparison, the difference in mean flux

279 between the 2-weekly averaged data of the on-line system and the 2-weekly estimates
280 from the ALPHA samplers gives an estimate of the chemical sampling error. This
281 chemical sampling error can be mostly associated with the on-line system, because it
282 only samples for part of the time (i.e. semi-continuous), as compared with the passive
283 system, which samples continuously.

284 **2.4 Other Uncertainties**

285 In order to further understand the uncertainties in the emission calculation, the input
286 variables were assessed for both field sites. The uncertainty caused by each variable
287 was estimated using WindTrax to back-calculate the consequent change in estimated
288 NH₃ emission. The total uncertainty was then calculated as the square root of the sum
289 of the squares of the individual uncertainties. Further details are provided in the
290 Supplementary Material Section 6.

291 **3. Results**

292 **3.1 Isle of May**

293 Active measurements and meteorological data

294 Measured NH₃ concentrations ranged from 0 to 105 µg m⁻³ and were found to be
295 lower during the morning and evening than during the day (Figure 4). Ground
296 temperature ranged from 12 to 27 °C and peaked during the early afternoon. The
297 roughness length estimated using the ultrasonic anemometer on the Isle of May
298 ranged from 0.1 to 13.8 cm, i.e., within the useable range of WindTrax. Ammonia
299 emissions generally followed a diurnal pattern with low emission early in the morning
300 (<5 µg m⁻² s⁻¹), building to a peak in the early afternoon (10 to 25 µg m⁻² s⁻¹), before
301 dropping back to low values (<5 µg m⁻² s⁻¹) in the evening (Figure 4). Overall, for the
302 active measurements the average emission rate was 5 µg m⁻² s⁻¹.

303 The uncertainty in background NH₃ concentration for the southern North Sea (0.03 -
304 1.49 µg m⁻³) resulted in an emission uncertainty of 6 %. The uncertainty in the size of
305 the NH₃ emission area (range of 0.2 – 0.3 km²), caused by puffins moving around
306 near their burrows during the day, resulted in an uncertainty in NH₃ emission of 10 %
307 (Supplementary Material Section 6). Considering only these components, the overall
308 uncertainty in the modelling of the emission estimate on the Isle of May is estimated
309 at 12 %. A major source of uncertainty is the representativity of the NH₃ sampling,
310 given that measurements were only made for part of the time, with the generator
311 having to be switched off during the hours of darkness. This is addressed further in
312 section 3.4.

313 <<INSERT FIGURE 4 HERE>>

314 Passive measurements

315 Ammonia concentrations decreased from a maximum of 36.1 µg m⁻³ during the first
316 period to a minimum of 0.9 µg m⁻³ during the fourth measurement period, due to
317 measurements being made towards the end of the breeding season. The NH₃ emission
318 was highest during Period 1 (01/07/09 - 15/07/09), estimated at 5.1 µg m⁻² s⁻¹. By mid-
319 July, most puffins had fledged and had left the nesting site. As a consequence, NH₃
320 emission decreased to 1.9, 0.4, 0.1 µg m⁻² s⁻¹ during measurement periods 2, 3 and 4,
321 respectively (for more details see Supplementary Material Section 7A). Temperatures
322 were broadly similar through the four sampling periods (Supplementary Material
323 Section 7A).

324 The uncertainty in the estimated emission caused by the roughness length, NH₃
325 background and emission area were 12, 8 and 10 %, respectively (See Supplementary
326 Material Section 6). The largest estimated uncertainty was the Monin-Obukhov length
327 at 28%. Overall, these factors contributed a combined uncertainty of ± 38 % to the
328 model results from the passive campaign on the Isle of May. However, this does not
329 include the micrometeorological uncertainty associated with long-averaging periods,
330 which is considered separately in Section 3.4.

331 **3.2 Bird Island, South Georgia**

332 Active measurements and meteorological data

333 The NH₃ concentrations measured by the AiRRmonia trace gas analyser were
334 between 0 and 60 $\mu\text{g m}^{-3}$, with higher concentrations recorded during the daytime
335 (Figure 5). Ground temperature ranged from 1 to 12 °C, with maximum values
336 during the early afternoon (Figure 5). The roughness length estimated from the ultra-
337 sonic anemometer on Bird Island ranged from 6 to 12.5 cm and was within the
338 useable range of WindTrax. Gras (1983) estimated open water background NH₃
339 concentration for Antarctica, a location representative of this area, at 0.15 $\mu\text{g m}^{-3}$,
340 which was used as the background concentration in WindTrax. The minimum and
341 maximum NH₃ emissions from the Big Mac penguin colony during the measurement
342 period were 0.6 $\mu\text{g m}^{-2} \text{s}^{-1}$ and 52.6 $\mu\text{g m}^{-2} \text{s}^{-1}$, respectively (Figure 5). The largest
343 emissions occurred during the daytime, associated with higher wind speeds (Figure
344 5), with smaller emissions at night.

345 The emission uncertainty caused by the uncertainty in the size of the excretion area,
346 again caused by penguins moving around the edge of the nesting site, and NH₃
347 background were estimated at 27 % and 4 %, respectively (Supplementary Material
348 Section 6). The combined uncertainty calculated for the modelled emission
349 estimate from the Big Mac penguin colony was at ± 28 %. The additional uncertainty
350 associated with the semi-continuous nature of the NH₃ measurements is examined in
351 Section 3.4.

352 <<INSERT FIGURE 5 HERE>>

353 Passive measurements

354 Ammonia concentrations nearest the colony (3 m from the edge of Big Mac)
355 decreased from a maximum of 34.2 $\mu\text{g m}^{-3}$ during the third period (21/11/2010 to
356 28/11/2010) to a minimum of 11.3 $\mu\text{g m}^{-3}$ during the fifth measurement period
357 (06/12/2010 to 12/12/2010; NH₃ concentration data is presented in Supplementary
358 Material Section 7B, full transect data to be published elsewhere (Tang et al. in prep.).
359 The NH₃ emission, calculated with WindTrax, was highest during Period 2 (Table 1),
360 estimated at 11.2 $\mu\text{g m}^{-2} \text{s}^{-1}$ and lowest during the fifth measurement period at 3.2 μg
361 $\text{m}^{-2} \text{s}^{-1}$.

362 The uncertainty in the estimated emissions caused by the roughness length, NH₃
363 background and emission area were 15, 12 and 12%, respectively (Supplementary
364 Material Section 6). The largest estimated uncertainty was associated with
365 micrometeorology at 35%. Overall, these amount to a combined uncertainty for the
366 passive campaign on Bird Island of ± 42 %.

367 **3.3 Signy Island**

368 On Signy Island the ALPHA samplers were exposed for three two-week periods
369 (Supplementary Material Section 7C). The NH₃ concentrations at Masts 1 and 2,

370 measured at a height of 1 m above the ground in the middle of the colony, were the
371 highest (maximum $483 \mu\text{g m}^{-3}$) of the different sampling locations at Signy. NH_3
372 concentration decreased with distance from the penguin colony to a minimum at Mast
373 5 (0.9 to $2.1 \mu\text{g m}^{-3}$). The ALPHA samplers lower to the ground (1 m height)
374 measured larger NH_3 concentration, as expected (see Supplementary Material Section
375 7C for details). The atmospheric conditions averaged over the measurement period
376 were estimated as neutral, (i.e. ($L = |\infty|$)) because of low ground heating and relatively
377 high wind (Seinfeld and Pandis, 2006). The most obvious sources of aerodynamic
378 roughness in the otherwise very flat area were the penguins (average height 60 cm)
379 and any larger rocks (maximum height estimated at 1 m). Therefore, a roughness
380 height of 10 cm, corresponding to an object height of 1 m (Seinfeld and Pandis,
381 2006), was used for modelling. The NH_3 source area was assumed to be the observed
382 nesting area, which was $2.7 \times 10^3 \text{ m}^2$.

383 The calculated NH_3 emission fluxes for the penguin colony on Signy Island were 18,
384 8 and $9 \mu\text{g m}^{-2} \text{ s}^{-1}$ for periods 1, 2 and 3, respectively. The wind was almost constantly
385 from the north-west, which suggests that the footprint of the source sampled by each
386 ALPHA sampler was not a very significant source of variation. The
387 micrometeorological conditions on Signy Island could only be estimated from
388 available data on Laurie Island, South Orkney Islands, and therefore a larger
389 uncertainty is associated with meteorological data needed to estimate NH_3 emissions.

390 The difference in the NH_3 emission rates between the first and second/third
391 measurement periods may be explained by the birds' behaviour, with colony
392 attendance during the first measurement period being high for both Adélie and
393 Chinstrap penguins. The lower emissions during the second and third periods may be
394 associated with the departure of the Adélie penguins around late January.

395 Together, the uncertainty in roughness length and stability resulted in an uncertainty
396 in emission of 26 % (Supplementary Material Section 6). The uncertainty associated
397 with background concentration from Gras (1983) was 7 % and the associated
398 uncertainty in area was estimated at ± 6 %. The combined uncertainty in modelling
399 NH_3 emissions for Signy Island was estimated at ± 37 %, although this does not
400 include uncertainty related to application of the time-integrated ALPHA sampling,
401 which is addressed in Section 3.4.

402 **3.4 Comparison of Active and Passive Sampling methods**

403 A summary of the measurements made at the different colonies of this study is
404 provided in Table 1. For the Isle of May, the mean fluxes from the passive and active
405 sampling campaigns were 5.1 and $5.3 \mu\text{g m}^{-2} \text{ s}^{-1}$, respectively. The estimate of the
406 flux from the active sampling averaged for the same period as the ALPHA
407 measurements was $6.0 \mu\text{g m}^{-2} \text{ s}^{-1}$. The difference between the first and third of these
408 fluxes represents the Uncertainty in Sampling Period (USP), at $-1.0 \mu\text{g m}^{-2} \text{ s}^{-1}$, while
409 the difference between the second and third of these represents the Uncertainty in
410 chemical Sampling Method (USM), at $-1.0 \mu\text{g m}^{-2} \text{ s}^{-1}$. In both cases the USP and
411 USM amount to around $\pm 20\%$ of the mean flux at Isle of May.

412 <<INSERT TABLE 1 HERE>>

413 A similar comparison of active and passive sampling at Bird Island gave a mean flux
414 during the first period from the passive and active sampling campaigns of 11.2 and
415 $10.3 \mu\text{g m}^{-2} \text{ s}^{-1}$, respectively. The mean fluxes during the second period from the
416 passive and active sampling campaigns were 8.9 and $10.5 \mu\text{g m}^{-2} \text{ s}^{-1}$, respectively.

417 The estimate of the flux from the active sampling averaged for the first and second
418 periods as the ALPHA measurements was 10.6 and $10.7 \mu\text{g m}^{-2} \text{s}^{-1}$, respectively. The
419 estimate of the flux from the active sampling averaged for the average of the two
420 periods of the ALPHA measurements was $10.7 \mu\text{g m}^{-2} \text{s}^{-1}$. In this case the USP
421 amounts to around 3% of the mean measured fluxes, whereas the USM was 6% for
422 the first period and 17% for the second period (Table 1).

423 In the case of Signy, only passive estimates of the flux were available, where the
424 overall mean of the three runs was $12 \mu\text{g m}^{-2} \text{s}^{-1}$. Although active sampling was not
425 possible at this site, the performance comparison distinguishing USP and USM at Isle
426 of May and Bird Island may be taken as an indication of the scale of uncertainty
427 associated with the long sampling periods on Signy.

428

429 **4. Discussion**

430 **4.1 Variation in NH_3 emissions from seabird colonies**

431 The largest weekly average NH_3 emission measured by this study was $18 \mu\text{g m}^{-2} \text{s}^{-1}$
432 on Signy Island, South Orkney Islands. Higher rates of NH_3 emission ($22 \mu\text{g m}^{-2} \text{s}^{-1}$)
433 were observed above the Brown noddy colony on Michaelmas Cay, Great Barrier
434 Reef, Australia (Riddick et al., 2014), while Blackall et al. (2007) reported even larger
435 emission rates equivalent to $240 \mu\text{g m}^{-2} \text{s}^{-1}$ from Atlantic gannets on the Bass Rock,
436 Scotland. These results illustrate how NH_3 emissions from seabird colonies are
437 considerable discrete NH_3 sources in a wide range of climates.

438 However, such figures tend to mask the climatic dependence of NH_3 emission, since
439 they are also a function of nesting density, and for total colony emissions, of bird
440 numbers, types and colony attendance, etc. It is therefore helpful to normalize the
441 emission rates per g of bird biomass. In this case, it can be seen that NH_3 emission is
442 much higher at the tropical colony ($7.5 \pm 2.6 \text{ mg NH}_3\text{-N g}^{-1} \text{ bird yr}^{-1}$; Michaelmas
443 Cay) than at the sub-polar Bird Island colony reported here ($0.05 \pm 0.01 \text{ mg NH}_3\text{-N g}^{-1}$
444 bird yr^{-1}).

445 Another way to normalize the NH_3 emission data is to calculate the percentage of
446 excreted nitrogen that volatilizes as NH_3 (P_v , %), as described in Supplementary
447 Material Section 8. An excretion rate (Furness et al., 1991; Wilson et al., 2004),
448 calculated from the adult/chick mass, nitrogen content of the food, energy content of
449 the food, assimilation efficiency of ingested food and proportion of time spent at the
450 colony during the breeding season has been used instead of direct measurements of
451 guano depth up at the colony to reduce disturbance to breeding birds and minimize the
452 risk of egg/chick abandonment. For the measurements reported here, a P_v value of
453 4.7 ± 0.5 % was calculated for the Atlantic puffin colony on the Isle of May,
454 compared with 1.6 ± 0.4 % for Bird Island and 3.1 ± 1.1 % for Signy Island,
455 respectively (percentage error in measurement and modelling; Table 1).

456 In Table 2 the values from the present study are compared with emission rates and
457 estimates of P_v from other published studies. This shows the largest values of P_v at
458 tropical colonies, such as the Brown noddy colony on Michaelmas Cay, where P_v was
459 estimated at 65 ± 22 % (Riddick et al., 2014), and the smallest values in sub-polar
460 conditions, with comparable values for Bird Island and Signy Island (2%, 3%,
461 respectively) and Cape Hallet on mainland Antarctica (2%, Theobald et al., 2013).
462 These observations are in agreement with Zhu et al. (2011) who also found that NH_3

463 emissions are larger under increased temperature. However, moisture limitation can
464 also be important at high temperatures.

465 As Riddick et al. (2014) showed for the two tropical islands, the higher value for
466 Michaelmas Island (67%) than for Ascension Island (32%) reflected a moisture
467 limitation at the latter site. In this instance, of two sites with similar temperatures, it
468 appears that the limited water availability at Ascension Island resulted in a lower rate
469 of uric acid hydrolysis, thereby leading to lower NH_3 emissions. By contrast, the
470 overall increase in observed P_v with increasing temperature across the sites (Table 2)
471 may be a consequence of both increasing volatility of NH_3 and increasing rates of uric
472 acid hydrolysis, where sufficient moisture is available, although it is not possible to
473 distinguish these component effects from our measurements. In order to examine
474 these drivers separately, specific process modelling is needed (Riddick, 2012; Riddick
475 et al. in prep).

476 <<INSERT TABLE 2 HERE>>

477 It is worth noting that the measured P_v for the Atlantic puffin colony on the Isle of
478 May (5%) is much lower than the estimate by Riddick et al. (2012) and the
479 measurements made in similar conditions on the rocky cliffs of the Isle of May
480 (Guillemot) and Bass Rock (Northern gannet) by Blackall et al. (2004; 2007) (16-
481 36%). The much lower emission rate for Atlantic puffins, compared with Northern
482 gannets and Guillemot under the same climate, may be attributed to their habitat
483 preference as burrow nesters in grassland. This illustrates how climatic conditions are
484 not the only factors to affect NH_3 emission. In the case of the puffins on the Isle of
485 May case, the comparison suggests that emissions rates are about 14-31% of what
486 would be emitted by bare-rock breeding birds under the similar temperate climatic
487 conditions.

488 Excretory behaviour of Atlantic puffins varies between individual birds and can lead
489 to variation in NH_3 emissions. The entrance chambers of most puffin burrows are free
490 from guano, with chicks deeper in the nest excreting inside the burrow, but adults do
491 not excrete in the burrow (M. Newell, pers. comm.). A significant fraction of the NH_3
492 emitted from subterranean excreta can therefore be expected to be absorbed by
493 overlying soil and vegetation. The amount of puffin excretion on the land surface
494 changes during the day as well as between days, puffins can be observed in large
495 numbers across the colony, often at dusk and less so at dawn (Harris & Wanless,
496 2011).

497 In earlier modelling estimates, the presence of substantial amounts of vegetation has
498 been estimated to reduce NH_3 by a multiplier of 0.2 (Wilson et al., 2004), while NH_3
499 emissions from excretion inside burrows was estimated to be 0.1 of that on bare rock.
500 Based on the P_v values presented in Table 2, the present measurements in the Firth of
501 Forth indicate 0.14 or 0.31 times lower emissions for Puffins (grass and burrows)
502 compared with Northern Gannets or Guillemots, respectively (which are both bare
503 rock breeders) which are broadly consistent with the prior model estimates.

504 **4.2 NH_3 Emissions and environmental conditions**

505 The NH_3 emission estimates from the on-line measurements offer the possibility to
506 compare and interpret emission rates with environmental parameters during the course
507 of the measurement campaigns. This is illustrated for the Isle of May and Bird Island
508 in the present study and for Ascension Island (Riddick et al., 2014), based on a
509 comparison of hourly emission estimates to each environmental variable (ground

510 temperature, relative humidity, wind speed and precipitation) at each site
511 (Supplementary Material Section 10).

512 The results show ground temperature is positively correlated to measured NH_3
513 emission at each site, representing tropical, temperate and sub-polar climates. The
514 strongest correlation with temperature was found at the Isle of May ($R=0.7$; $P<0.001$).
515 Conversely, the weakest correlation between ground temperature and NH_3 emissions
516 was found for Ascension Island ($R=0.2$; $P<0.001$), which appears to have been due to
517 the overriding importance of moisture-limitation on the temporal pattern of emissions
518 at this site (Riddick et al., 2014). This is illustrated by a higher correlation between
519 NH_3 emission and relative humidity ($R = 0.4$; $P<0.001$) and NH_3 emission and
520 precipitation events ($R = 0.3$; $P<0.001$) at Ascension Island. In fact, Ascension is the
521 only field site where there is a positive correlation between NH_3 emission and both
522 relative humidity and precipitation, whereas relative humidity is inversely correlated
523 to emission at the Isle of May and Bird Island. This indicates that, where there is
524 sufficient water availability for uric acid hydrolysis (as at Bird Island and the Isle of
525 May), excess water tends to suppress the measured NH_3 emission.

526 Wind speed has a positive correlation with emission at all sites, with this correlation
527 being strongest in the sub-polar conditions of Bird Island ($R = 0.9$; $P<0.001$) and
528 weakest in the tropical conditions of Ascension Island ($R = 0.1$; $P=0.09$). This may
529 reflect the fact that Bird Island is the windiest site ($2 - 18 \text{ m s}^{-1}$) with the smallest
530 moisture limitation and temperature variation, so that turbulence is the major
531 controller of hourly variation in NH_3 emissions. By contrast, wind speeds were lower
532 at Ascension Island, so that the effect of varying moisture limitation largely masked
533 the effect of wind speed.

534 It was assumed that the pH at each site remained constant throughout. No direct
535 measurements of pH were taken because of access restrictions to the breeding sites
536 and changes in pH of the guano may explain some of the variance in results.
537 Supplementary Material Section 11 shows there is some correlation between soil pH
538 and P_v ($R^2 = 0.40$, number of points = 11, p-value 0.04). Supplementary Material
539 Section 11 also shows that there is also a negative correlation between seabirds' food
540 energy to nitrogen ratio ($R^2 = 0.61$, number of points = 11, p-value 0.004). The
541 energy to nitrogen ratio is significantly correlated to P_v , but that the response is very
542 weak as the ratio only goes from 167 to 189, ie around 10% variation, so cannot
543 propagate much to other estimates, and may simply reflect input uncertainty in the
544 dataset. The sample size of species and diet is very small and further investigation is
545 required to ensure this is not correlated solely with temperature.

546 **4.3 Comparison of Active and Passive sampling methods**

547 The comparison summarized in Table 1 shows that the approach of calculating time-
548 averaged NH_3 fluxes from ALPHA samplers provided surprisingly similar estimates
549 to those calculated from on-line sampling with 15 minute averaging. This finding is
550 consistent with a similar comparison by Riddick et al. (2014) for tropical colonies,
551 and by Theobald et al. (2013) for measurements on mainland Antarctica. In principle,
552 while co-variance between NH_3 concentrations and varying atmospheric turbulence is
553 expected to lead to significant errors, these comparisons show that the errors
554 associated with this can be relatively modest in practice. While this finding may be a
555 surprise to micrometeorologists, it appears to result from the fact that non-linearities
556 associated with averaging over periods of changing atmospheric stability are

557 relatively modest when compared with other sources of uncertainty, especially for
558 such sites at relatively windy locations.

559 By calculating the flux using the on-line NH₃ sampling, but with the time resolution
560 of the ALPHA samplers, we can also compare the chemical and meteorological
561 sources of uncertainty. In this way, Table 1 shows that the Uncertainty associated
562 with the Sampling Period (USP) is of comparable magnitude to the Uncertainty
563 associated with the chemical Sampling Method (USM). This study therefore further
564 provides support for the utility of low-cost passive sampling measurements at remote
565 locations where it is often logistically much harder to deploy expensive active
566 sampling methods. While such passive NH₃ flux measurements cannot replace
567 continuous measurements for the examination of detailed (e.g. hourly) temporal
568 controls on emissions (Supplementary Material Section 10), they may serve a useful
569 role in gathering data over longer periods (e.g. 2-weekly measurements over several
570 years) for comparison of seabird colonies in different climates.

571 **5. Conclusions**

572 The analysis shows that each of the environmental variables investigated have an
573 influence on NH₃ emission (ground temperature, relative humidity, precipitation,
574 wind speed). Increases in NH₃ emission caused by increases in relative humidity and
575 rain events were only observed at the arid Ascension Island field site, where lack of
576 moisture appeared to limit rates of uric acid hydrolysis. At other sites in colder
577 climates, increases in precipitation result in decreased NH₃ emission, because rain
578 events dilute available ammonium pools, while having the potential to wash uric acid
579 and NH₃ from the surface. Ammonia emission was found to increase with wind speed
580 especially at the cooler sites, reflecting a reduction in both aerodynamic and boundary
581 layer resistances at higher wind speeds. Overall, the most consistent relationship is
582 the increase in NH₃ emission with increasing ground temperature.

583 Future work will examine these mechanisms more explicitly using a mechanistic
584 model (Blackall, 2004; Riddick, 2012), allowing the observed relationships between
585 environmental conditions and NH₃ emission to be better understood, as well as
586 providing a basis for simulating the effect of future climate change scenarios on
587 global NH₃ emissions from seabird colonies.

588 **Acknowledgements**

589 This work was supported by a grant from the NERC CEH Integrating Fund and
590 jointly carried out between the Centre for Ecology & Hydrology and King's College,
591 London. Thanks to D. Briggs of BAS on Signy for information on meteorology and
592 nesting penguins, and the BAS Bird Island crew for their technical and physical
593 support (BAS CGS grant). Thanks to the CEH seabird group and other researchers
594 on the Isle of May, especially to M. Harris, T. Alampo and D. Pickett (the last two
595 from Scottish National Heritage). Special thanks to A. Easton and C. Murray for
596 transport to and from the Isle of May.

Figure 1 Left pane: Location of the Isle of May off the coast of Scotland, UK (56.19 °N, 2.56 °W). Right pane: Details of the Isle of May showing the Atlantic Puffin study colony, meteorological station and the site for on-line campaign measurements of ammonia concentration.

Figure 2 Top left pane: Location of measurement site on South Georgia (54.01 °S, 38.08 °W). Bottom left pane: Location of Bird Island in relation to South Georgia. Right pane: North western Bird Island indicating locations of Big Mac Macaroni penguin colony being studied, location of passive samplers and the site of the active ammonia concentration measurements, at Fairy Point.

Figure 3 Top left pane: Location of measurement site on South Orkney Island (60.73 °S, 45.59 °W). Bottom Left pane: Location of Signy Island relative to the South Orkney Islands. Right pane: Details of south-eastern Signy Island showing the ammonia sampling locations (ALPHA masts) in relation to the studied nesting area of Adélie and Chinstrap penguin nests on the Gourlay Peninsula of Signy Island.

Figure 4. Time-course of measured ammonia concentrations (top), calculated NH₃ emissions (bottom) for the active sampling campaign on the Isle of May, Scotland July 2009.

Figure 5 Time-course of measured ammonia concentrations (top), calculated NH₃ emissions (bottom) for the active sampling campaign on Bird Island, South Georgia, November & December 2010.

Table 1 Comparison of active and passive sampling. Summary of seabird colony NH_3 emissions estimated from temperate and sub-polar measurement campaigns. P_v is the percentage of excreted nitrogen that volatilizes as NH_3 , Ground T is the ground temperature, USP represents the uncertainty in the flux attributable to the choice of sample averaging period and USM represents the uncertainty in the flux caused by the choice of sampling method (see notes below). Colony M indicates Isle of May, colony B indicates Big Mac on Bird Island and colony S indicates Signy Island.

Table 2 Summary of seabird colony NH_3 emissions estimated from measurement campaigns at the field sites in this study as compared with other recent measurements. Column P_v describes the percentage of seabird excreted nitrogen that volatilizes as NH_3 .

Colony	Measurement Period	Passive				On-line measurement								USP ($\mu\text{g m}^{-2} \text{s}^{-1}$)	USM ($\mu\text{g m}^{-2} \text{s}^{-1}$)
		[NH ₃] ($\mu\text{g m}^{-3}$)	Av. Flux NH ₃ ($\mu\text{g m}^{-2} \text{s}^{-1}$) (Flux a.)	Uncertainty in flux \pm ($\mu\text{g m}^{-2} \text{s}^{-1}$)	P_v (%)	Av. Flux NH ₃ ($\mu\text{g m}^{-2} \text{s}^{-1}$) (Flux b.)	Uncertainty in flux \pm ($\mu\text{g m}^{-2} \text{s}^{-1}$)	P_v (%)	Av. [NH ₃] ($\mu\text{g m}^{-3}$)	Flux using Av. [NH ₃] ($\mu\text{g m}^{-2} \text{s}^{-1}$) (Flux c.)	Uncertainty in flux \pm ($\mu\text{g m}^{-2} \text{s}^{-1}$)	P_v (%)

¹ Ammonia concentrations measured in the middle of the colony (Passive Measurement site, Isle of May) and 1.5 m from the ground

² Ammonia concentrations measured at 3 m from the edge of the colony (Mast 1, Bird Island) and 1 m from the ground

³ Ammonia concentrations measured in the middle of the colony (Mast 1, Signy Island) and 1 m from the ground

⁴ Ammonia concentrations measured in the middle of the colony (Active Measurement site, Isle of May) and 1.26 m from the ground

⁵ Ammonia concentrations measured at 300 m from the edge of the colony (Active Measurement site, Bird Island) and 2 m from the ground

Notes:

Flux a. Flux calculated as the mean (+/- uncertainty) of hourly flux estimates based on hourly meteorology and time-integrated NH₃ concentrations from passive sampling

Flux b. Flux calculated as the mean (+/-uncertainty) of available hourly flux estimates derived from application of the on-line hourly NH₃ measurements with hourly meteorology.

Flux c. Flux calculated as the mean (+/-uncertainty) of flux estimates calculated from the on-line NH₃ measurements based on block averaging the NH₃ concentrations to the same extended sampling periods as used for the passive sampling.

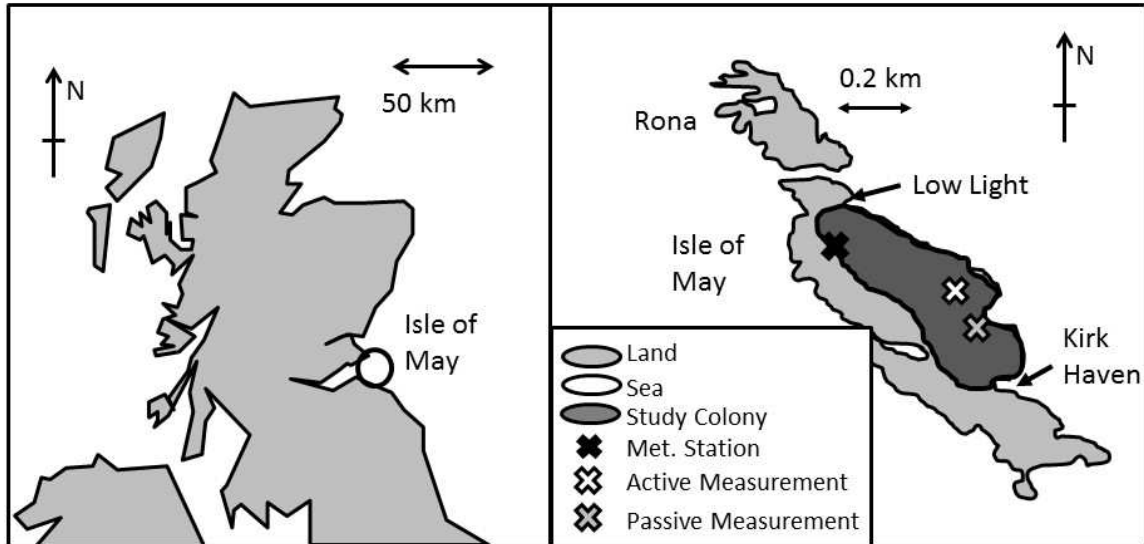

USP is calculated as flux b minus flux c, and estimates the uncertainty in flux a and c due to using time-integrated NH_3 sampling instead of continuous hourly NH_3 concentrations. USM is calculated as flux a minus flux c, and estimates the uncertainty in flux b and c due to incomplete sampling when using the on-line measurement system.

>The effect of meteorology on NH_3 fluxes from temperate and sub-polar seabird colonies is measured. >The percentage of excreted nitrogen that volatilized was 3% at sub-polar penguin colonies. > The percentage of guano nitrogen volatilized in temperate and sub-polar environments is much smaller than in tropical contexts. > Confirms that temperature has a significant influence on the magnitude of NH_3 emissions.
